How much sick leave is work-related?

Abstract

Background. Sick leave is a topical subject, particularly following the revision of the Agreement on a More Inclusive Working Life (the IA agreement). However, there has been little discussion about the extent to which sick leave may be related to work.

Material and methods. The paper is based on a non-systematic literature search using PubMed combined with personal research and experience.

Results. Various studies indicate that a significant proportion of all sick leaves may be due to illness caused by working conditions. Heavy physical work, awkward work postures and low job control are particularly important factors. People who suffer from work-related illnesses have a greater need for absence from work than people with similar illnesses caused by factors other than their work. Workplace interventions designed to prevent work-related illness may also prevent sick leave. Sick leaves which are due to an illness may also prevent sick leave. Sick leaves which are due to illness caused by factors related to work may often be prevented or shortened by workplace interventions, irrespective of what causes the imbalance.

Interpretation. It is my view that more attention should be attached to primary preventive measures to reduce sick leave, particularly following the revision of the Agreement on a More Inclusive Working Life (the IA agreement).

Material and methods

The paper is based on a non-systematic literature search using PubMed and a discretionary selection of articles based on personal knowledge of the field and experience gained through my own studies.

What does «work-related» mean?

All sick leave may be said to be work-related in the sense that the employee finds it difficult to carry out his/her job due to illness, i.e. health-related work problems. However, this definition is not particularly useful in terms of workplace prevention. «Work-related health problems» are often defined as health problems (illness or injury) which are partly or entirely caused or aggravated by working conditions (5–7). Workplace intervention may prevent or reduce such health problems as well as the resulting sick leave.

Is there a causal link between work and ill health?

The relationship between certain working conditions and ill health is well documented. As early as in 1700 Italian physician Ramazzini listed diseases associated with more than 50 occupations (8). In Finland, it is estimated that 7 per cent of all fatalities in the relevant disease and age categories may be attributed to occupational factors, a higher proportion among men (10 per cent) than among women (2 per cent), and a total of 4 per cent of all fatalities, irrespective of age and diagnosis (9). It is estimated that approximately 20 per cent of lung cancers among Norwegian men would have been avoided were it not for occupational exposure (10, 11). The same applies for 85 per cent of all malignant mesotheliomas, a type of cancer which is most often caused by asbestos exposure at work, and 32 per cent of nasal and sinus cancers (10). Based on epidemiological literature, the American Thoracic Society estimates that approximately 15 per cent of asthma instances among adults, and 15 per cent of COPD (chronic obstructive pulmonary disease) in the general population, may be attributed to work (12).

Work-related health problems are very common. Approximately 60 per cent of respondents in the Oslo Health Study (the HUBRO study) reported that they had suffered from health problems caused by working conditions in the course of the last month (13). Neck/shoulder pain and low back pain were the most common; these were attributed to working conditions by respectively 3/4 and 1/2 of the respondents with such pain. The data included health problems of all severities and it is probable that people with light symptoms rarely take sick leave. Statistics Norway’s Level of living survey 2006 showed that among the economically active with work-related musculoskeletal disorders, approx. 15 per cent reported to suffer «great pain» and 25 per cent «some pain»; the corresponding figures for respon-
Self-reported work-related illness

In the Level of living survey 2006, 18 per cent of all economically active respondents reported that they had taken at least one sick leave of more than 14 days’ duration in the course of the last 12 months. Approximately 40 per cent of them answered that their absence was due to health problems which partly or entirely was caused by their job (21). This constitutes 7 per cent of the working population, somewhat higher among women (8 per cent) than among men (5 per cent). A similar figure (7 per cent of the working population) was found in a later survey of work-related illnesses and injuries in connection with Statistics Norway’s Labour force survey 2007, involving slightly different questions (22). The data showed great variation with occupation, ranging from less than 1 per cent in the group of doctors, dentists, pharmacists and veterinary surgeons to 13 per cent among cleaners, food workers, cooks and catering assistants.

The proportion of sick leaves that were reported to be work-related varied significantly as well, from 5 per cent to 50 per cent for the above-mentioned occupations (21).

Tellnes et al. conducted a study of sick leave among 118 GPs and their patients in the Buskerød area and found that heavy physical work was assessed by the doctor and/or patient to be a contributing cause of the illness leading to sick leave in 48 per cent of patients (23). The work-related proportion was considerably higher among patients with musculoskeletal disorders (78 per cent), particularly if they were involved with heavy physical work or were standing or walking a great deal at work (in excess of 90 per cent). Psychological factors associated with work were considered to be a contributing cause of illness for 32 per cent of absentees. There were great variations depending on the type of health problem and the type of work.

Can we trust self-reporting?

Questionnaires are often used to investigate work-related health problems; this is the case for Statistics Norway’s Level of living surveys as well as the European Working Conditions Surveys (24). Many have a sceptical attitude to this kind of self-reporting and hold the opinion that the individuals themselves will tend to over-estimate the correlation with work. The HUBRO study compared self-reporting to physician assessment for 217 people suffering from neck/shoulder or arm pain (25). The doctors used criteria drawn up by a group of European experts to assess whether the pain might be caused by working conditions (26). The sufferers themselves considered their pain to be work-related slightly more often than the physicians: 80 per cent versus 65 per cent for neck/shoulder pain, and 78 per cent versus 72 per cent for arm pain. Consequently, self-reporting appears to give a reasonably good measure of the work-related proportion of health problems, but this may vary with the type of health problem and the criteria for assessing the work-relatedness (25).

Work-related illness and work capacity

There is much evidence that people with work-related health problems have more sick leaves than people with similar health problems caused by factors other than their work. Individuals who are taken ill for reasons associated with their work will evidently have a greater need for absence from the work that made them ill. Leira et al. surveyed people who had been on sick leave for more than 16 days due to asthma and found that as much as 70 per cent had work-related asthma, based on reports of respiratory symptoms suffered at work and improving symptoms when absent from work (27). This is significantly higher than in the general population, as demonstrated, for instance, by the HUBRO study which showed that 18 per cent of people with asthma symptoms attributed their symptoms to work (13). A Finnish study showed that the risk of full incapacity to work was nearly 13 times higher among patients who reported work-related health problems than among those who reported non-work-related health problems (28).

The significance of work environment factors

A number of work-related factors have been studied in relation to sick leave, particularly physical/ergonomic factors such as heavy physical work, awkward work postures and repetitive work, psychosocial working conditions such as psychological job demands, job control and social support in the workplace, and organisational factors such as shift work. A comprehensive study of the causes of sick leave carried out in 2004 (29) found limited scientific evidence that physical working conditions – particularly heavy physical work – have an effect on sick leave, and moderate evidence of a causal connection with low job control (30). However, among people who were sick-listed due to back disorders, it was found that a number of factors had an effect, among them low job satisfaction (moderate documentation), low job control, and work involving heavy lifting or a bent/twisted working position (limited documentation) (31). Despite a great number of studies and well documented statistical associations between working conditions and sick leave, it was nevertheless concluded that the scientific documentation to support a causal relationship was generally limited, especially due to

**Figure 1** Simple model showing the relationship between work and sick leave
problems with selection or confounding (30). Even if the association between disease and certain working conditions is well documented, most people who suffer from a disease are not on sick leave, a fact which may contribute to the relatively weak documentation (32).

In Denmark a number of longitudinal studies have been conducted in which attempts have been made to reduce the weaknesses of earlier research (33). These studies have combined the use of data from questionnaires and records, and they have studied factors that impact on different stages of the sick leave process (34).

They estimated that the number of people taking more than six sick days per year could have been 40 per cent lower if everyone’s physical and psychosocial working environment had matched the standard of that enjoyed by the 10 per cent with lowest exposures (35). Other studies from Denmark have shown similar figures (36). Heavy physical work such as heavy lifting/carrying or pushing/pulling, and awkward work postures such as standing up/squatting or a bent/twisted neck/back, appear to be particularly important (37). Many psychosocial job factors appear to be important, such as job control (work autonomy), social support from supervisors, psychological job demands, predictability and role conflicts (33, 38). The results vary somewhat from study to study and between women and men, particularly with respect to psychosocial factors (33). The attributable proportion of sick leave was found to be higher for work-related factors than for lifestyle factors such as smoking (26 per cent among women and 17 per cent among men) (39).

Social inequalities in health are well documented and working conditions have been shown to influence these differences (40). A Danish study found that physical and psychosocial working conditions could explain as much as 40–50 per cent of long-term sick leave differences between the highest and the lowest social classes (managers/academics and skilled/unskilled workers respectively), adjusted for lifestyle and other factors (41).

The significance of structural working conditions

Many studies have shown that structural conditions, such as re-organisation and workforce downsizing, can bring higher rates of sick leave, disability retirement and mortality in the following years (42–46). This is the case for people who are directly affected (42, 43) but also for people who remain in the company after it has been downsized (43, 46). Tougher job demands, lower job control and higher job insecurity in connection with the downsizing are all factors shown to have an impact on health and sick leave (47). A project entitled «The New state» found that the increase in sick leave in the Norwegian Postal Service and the Public Roads Administration/Mesta after the workforce was downsized in the mid 1990s, could largely be explained by longer periods of sick leave (44). However, other studies have indicated unaltered or lower rates of sick leave after downsizing operations (48, 49). This is interpreted as «sickness presenteeism», i.e. that people attend work even if they are ill, particularly people in time restricted employment or with lower job security (46, 48).

Preventing sick leaves caused by work-related illness

Incapacity to work is a relational concept and must be seen in the context of the individual’s resources and the demands he/she encounters at work (18). If there is a mismatch between an individual’s level of functional ability and his/her job demands, this may give rise to problems in carrying out the work and therefore a need for sick leave (50). This type of imbalance may be caused by illness and impaired health while job demands remain unaltered, or by increasing job demands while health and functional ability remain the same, for example in connection with a restructuring process or workforce downsizing (18). There will often be a combination of the two varieties.

Workplace interventions to prevent work-related illness may also prevent sick leave. Furthermore, such workplace initiatives may often make it possible to prevent or shorten sick leave periods caused by an imbalance between individual resources and job demands, irrespective of the primary cause of the imbalance. This will apply to most cases of sick leave, which therefore must be considered work-related in a wider sense. This will include «job related functional absence», but also to a great extent «relative functional absence» as per Brøngård & Clausen’s categorisation of sick leave (51).

At the moment there is relatively limited documentation available concerning the effect of workplace intervention on sick leave. A recently published Cochrane review based on six randomised controlled trials concluded that there is moderate-quality evidence to support the use of workplace interventions to reduce sick leave among workers with musculoskeletal disorders when compared to usual care (52). More recent randomised intervention studies have shown that the screening of employees by an occupational health assessment followed by intervention vis-a-vis people with a higher risk of long-term sick leave, may produce a 30–40 per cent reduction in the number of sick days (53–55).

Workplace interventions aimed at pregnant women have been shown to reduce sick leave during pregnancy. A project carried out in the South Troms area demonstrated a reduction in the average length of sick leaves from approx. 16 to 2.4 weeks (85 per cent), while the use of graded sick leave increased (56). A study based on the Norwegian Mother and Child Cohort Study confirms the importance of making job adjustments to accommodate pregnant women. Kristensen et al. found that half the pregnant women who experienced a need for job adjustments but who had never benefited from such, took more than two weeks of sick leave between week nos. 17 and 30 of the pregnancy, whereas women who had benefited from such arrangements had an 11 per cent lower risk (57).

Discussion

This literature review shows that sick leave is often work-related, either in a narrow sense, when the absence from work is caused by work-related illness or injury, or in a wider sense, when the absence is caused by an imbalance between individual resources and job demands. In both cases workplace interventions may prevent or shorten the period of sick leave.

Many resources are expended on initiatives designed to help the sick return to work, by doctors, employers and the Norwegian Labour and Welfare Administration (NAV). However, more importance should be attached to primary preventive measures designed to reduce work-related illness and workplace interventions designed to accommodate people who carry a higher risk of absence, before they get sick-listed. For many, it will take a long time before they are capable of resuming work.

Employers have an obvious responsibility, but often fail to see the need to take action before the employee falls seriously ill or has taken sick leave. Medical practitioners may see the need, but are often insufficiently briefed on work-related matters and have no contact with employers. The occupational health service possesses knowledge about the relationship between work and health and also has a route of contact with the employer. The occupational health service should play a central part in this context, but its role remains obscure within the current IA agreement. The service is probably underused by everyone ranging from the treating physicians to the employers, the employees and the Norwegian Labour and Welfare Administration.

The IA agreement has three objectives, but so far most of the focus has been on reducing sick leave. Measures that help us succeed in including the elderly and those with reduced work capacity will enable these people to remain in employment, albeit with a somewhat higher rate of absence. This may however be a low price to pay for keeping as many as possible in employment?

I would like to thank Helge Kjus at the National Institute of Occupational Health for providing his comments on my manuscript.
